

Boolean chains *

Alberto Paoluzzi

February 8, 2016

Abstract

A novel algorithm for computation of Boolean operations between cellular complexes is given in this module. It is based on bucketing of possibly interacting geometry using a box-extension of kd-trees, normally used for point proximity queries. Such kd-tree representation of containment boxes of cells, allow us to compute a number of independent buckets of data to be used for local intersection, followed by elimination of duplicated data. Actually we reduce the intersection of boundaries in 3D to the independent intersections of the buckets of (transformed) faces with the 2D subspace $z = 0$, in order to reconstruct each splitted facet of boolean arguments, suitably transformed ther together with the bucket of indent facets. A final tagging of cells as either belonging or not to each operand follows, allowing for fast extraction of Boolean results between any pair of chains (subsets of cells). This Boolean algorithm can be considered of a *Map-Reduce* kind, and hence suitable of a distributed implementation over big datasets. The actual engineered implementation will follow the present prototype, using some distributed NoSQL database, like MongoDB or Riak.

1 Introduction

2 Preview of the algorithm

The whole Boolean algorithm is composed by four stages in sequence, denoted in the following as *Unification*, *Bucketing*, *Intersection*, and *Reconstruction*. The algorithm described here is both multidimensional and variadic. Multidimensional means that the arguments are solid in Euclidean space of dimension d , with d small integer. The *arity* of a function or operation is the number of arguments or operands the function or operation accepts. In computer science, a function accepting a variable number of arguments is called *variadic*.

2.1 Unification

In this first step the boundaries of the n Boolean arguments are computed and merged together as a set of chains defined in the discrete set V made by the union of their vertices, and possibly by a discrete set of points generated by intersection of cells of complementary dimension, i.e. whose dimensions add up to the dimension of the ambient space. Actually, only the (*oriented*) boundaries V, FV_i ($1 \leq i \leq n$) of the varius arguments are retained here, and used by the following steps of the algorithm.

2.2 Bucketing

The bounding boxes of facets FV_i are computed, and their *box-kd-tree* is worked-out, so providing a group of buckets of close cells, that can be elaborated independently, and possibly in parallel, to compute the intersections of the boundary cells.

2.3 Intersection

For each facet f of one of Boolean arguments, the subset $F(f)$ of incident or intersecting facets of boundaries of the other arguments were computed in the previous *bucketing* step. So, each F is transformed by the affine map that sends f into the $z = 0$ subspace, and there is intersected with this subspace, generating a subset $E(f)$ of coplanar edges. This one is projected in 2D, and the *regularized* cellular 2-complex $G(f)$ induced by it is computed, and mapped back to the original space position and orientation of f (providing a partition of it induced by the other boundaries).

2.4 Reconstruction

Like for in the reconstruction of 2D solid cells using the angular ordering of edges around the vertices, the coincident edges are identified in 3D , and used to sort the incident faces sing vhe falues of solid angles given with one reference face. The 3D space partition induced by $\cup_f G(f)$ is finally reconstructed, possibly in parallel, by traversing the adjacent sets of facets on the boundary of each solid cell.

3 Implementation

3.1 Box-kd-tree

3.2 Merging the boundaries

3.3 Elementary splitting

In this section we implement the splitting of $(d - 1)$ -faces, stored in `FV`, induced by the buckets of $(d - 1)$ -faces, stored in `parts`, and one-to-one associated to them. Of course,

(a) both such arrays have the same number of elements, and (b) whereas `FV` contains the indices of incident vertices for each face, `parts` contains the indices of adjacent faces for each face, with the further constraint that $i \notin \text{parts}(i)$.

Submanifold mapping computation The 4×4 (affine) `scipy` matrix `transform` of type `mat` is computed by the function `submanifoldMapping`, using as input the array `pivotFace` that contains the vertices of the so-called *pivot* face, i.e. of the face to be mapped to the coordinate subspace $z = 0$ (in 3D).

```
⟨ Submanifold mapping computation 4a ⟩ ≡
    """ Submanifold mapping computation """
    def submanifoldMapping(pivotFace):
        tx,ty,tz = pivotFace[0]
        transl = mat([[1,0,0,-tx],[0,1,0,-ty],[0,0,1,-tz],[0,0,0,1]])
        facet = [ VECTDIFF([v,pivotFace[0]]) for v in pivotFace ]
        m = faceTransformations(facet)
        mapping = mat([[m[0,0],m[0,1],m[0,2],0],[m[1,0],m[1,1],m[1,2],0],[m[2,0],
            m[2,1],m[2,2],0],[0,0,0,1]])
        transform = mapping * transl
        return transform

Remove intersection points external to a submanifold face When computing the LAR of each submanifold face embedded in $z = 0$ hyperplane, it is necessary to remove every vertex that was generated, outside the considered input face, by intersection of (incident) edges. This would produce spurious topology, i.e. cells that do not find adjacents cells incident to their boundaries.

```
<Remove intersection points external to a submanifold face 6b> ≡
    """ Remove intersection points external to a submanifold face """
    def veryClose(p,q):
        out = False
        if VECTNORM(VECTDIFF([p,q])) <= 0.002:

Space partitioning via submanifold mapping the function `spacePartition`, given in the below script, takes as input a *non-valid* (with the meaning used in solid modeling field — see [Req80]) LAR model of dimension $d - 1$, i.e. a triple (V, FV, EV) , and an array `parts` indexed on faces, and containing the subset of faces with greatest probability of intersecting each indexing face, respectively. The `spacePartition` function returns the *valid* LAR boundary model (W, FW, EW) of the space partition induced by FV .

```

⟨ Space partitioning via submanifold mapping 7 ⟩ ≡
    """ Space partitioning via submanifold mapping """
    def spacePartition(V,FV,EV, parts):
        FE = crossRelation(len(V),FV,EV)

3.4 Circular ordering of faces around edges

3D boundary triangulation of the space partition The function `boundaryTriangulation` given below is used to guarantee that there is a unique (simple) facet incident to an edge and contained in one LAR facet. More clearly, the Boolean decompositions generated by LAR allow for non convex cells, and in particular for nonconvex boundary facets of d -cells. This fact may induce errors in the computation of circularly sorted faces around edges. Conversely, by decomposing the faces into triangles, such ordering problems cannot appear. We also note that whereas every $(d - 1)$ -facet is made by coherently oriented triangles, it is not possible to give—a priori—a coherently orientation to all the facets, since the object interior and exterior are not defined (for now).

```

Edge-triangles to Edge-faces incidence In the function `ET_to_EF_incidence` below, we convert the Edge-triangles incidence table `ET_angle` to a Edge-faces incidence table `EF_angle`. The input data to the algorithm are the relations `TW, FW`, and, of course, the incidence `ET_angle`. It works by computing two translationa tables `tableFT` and `tableTF` from face indices to triangle indices and viceversa. Of course, `assert(len(EF_angle) == 2*len(FW))` must be True.

```

<Edge-triangles to Edge-faces incidence 13> ≡
""" Edge-triangles to Edge-faces incidence """
def ET_to_EF_incidence(TW,FW,FT, ET_angle):
    tableFT = FT
    tableTF = invertRelation(tableFT)
    EF_angle = [[tableTF[t][0] for t in triangles] for triangles in ET_angle]
    #assert( len(EF_angle) == 2*len(FW) )
    return EF_angle

```

Cells from $(d-1)$ -dimensional LAR model Since faces in the space partition induced by overlapping 3-coverings are $(d-1)$ -cells, they are located on the boundary of *two* d -cells of the partition. Hence, the traversal algorithm of the data structure storing the relevant information may be driven by signing the two cofaces of each face as being either already visited or not.

3.5 Progressive reconstruction of 3-cell boundaries

The input to this stage is a 2-complex embedded in 3D, with 2-cells non necessarily convex. The output is the 3-space partition defined by the cellular 3-complex, whose 2-skeleton is the input complex. In other words, we must reconstruct the 3-cells induced by the 2-cells of the input complex. This is done reconstructing the 3-cells stepwise. Each 3-cell reconstruction is done starting from one face two-dimensional previously taken into account no more than one single time, so that every 2-face is used at most exactly twice. An example of use of the functions implemented in this section is given in example `test12.py`

Edge cycles associated to a closed chain of edges The problem here is to conserve in the new `cycles` the same orientation of the previous ones, passed through the `orientedEdges` variable. We can formalize the problem as follows. Let call `pcycles` (for “previous cycles”) and `fcycle` (for “face cycle”) the algorithm input. The output is the *coherently oriented* `outcycles`. First, an orientation is given to `fcycle`; then this one is compared with the `pcycles` orientation, and it is possibly reversed, in order to get them coherently oriented. Finally, the direct sum of `pcycles` and `fcycle` is executed, giving the `outcycles`.

```
< Cycles orientation 14 > ≡
    """ Cycles orientation """
    def cyclesOrient(pcycles,fcycle,EV):
        if set(AA(ABS)(pcycles)).difference(fcycle)==set(): return []
        ofcycle,_ = boundaryCycles(fcycle,EV) # oriented
        ofcycle = ofcycle[0] # oriented
        if type(pcycles[0])==list: opcycle = CAT(pcycles)
        else: opcycle = pcycles
        int = set(opcycle).intersection(ofcycle)
        if int != set():
            ofcycle = reverseOrientation(ofcycle)
        outChain = [e for e in ofcycle if not (-e in opcycle)]
        outChain += [e for e in opcycle if not (-e in ofcycle)]
        return outChain

    if __name__ == "__main__":
        pcycles = [[-19, 13, 22, 23]]
        fcycle = [30, 20, 18, 2, 26, 19]
```

3-cell traversal The following script contains a completely reviewed and rewritten version of the extraction of 3-cells from its 2-skeleton embedded in 3D. The number of boundary edges of general LAR 2-faces is given by `len(EF_angle)` or by `len(ET)`. The array `len(EV)` has length `len(EF_angle)` + the number of added edges due to the triangulation of original faces. The added edges are not returned inside `FE` and `EF_angle`.

$\langle 3\text{-cell traversal 15a} \rangle \equiv$

◊

Macro referenced in 23.

The 3-cell traversal algorithm Initially, the list of counterclockwise ordered faces around the oriented edges are computed, and stored as indexed by edges in the `EF_angle` list of lists. This information is stored in the compressed sparse row matrix `csrEF`, whose element (e, f) provides the *next* face index incident on edge e , after f .

Also, a list of list of zeros is stored in the `visitedFE` variable, in order to memorize the visited pairs (f, e) by writing one in their corresponding positions. The `firstSearch` function will so retrieve the first non visited pair, in order to start the extraction of a new 3-cell. The `cv` variable accumulates the vertex indices of the current 3-cell. When the 3-cell is completely extracted (how-to test?), will be stored as a new row in the `CV` relation.

The test for completeness of the extraction is done by computing the current boundary of the cell as a set of edges of faces, by python `XOR` of the edges of every accumulated face-edge relation. When this set it becomes empty, the 3-cell extraction is completed.

Start a new 3-cell The function `startCell` below is used to begin the extraction of a new 3-cell (after the first one was already extracted). Therefore its aim is to choose as

first face one already previously extracted, in order to begin the current boundary with one cycle coherently oriented. This will be implemented by looking for a “face” position stored in `visitedCell` with just one `None` value in its row.

```
<Start a new 3-cell 16> ≡
    """ Start a new 3-cell """
    def startCell(visitedCell,FE,EV):
        if len([term for cell in visitedCell for term in cell if term==None]) == 1: return -1,-1
        for face in range(len(visitedCell)):
            if len([term for term in visitedCell[face] if term==None]) == 1:
                edge = visitedCell[face][0]
                break
            else: pass #TODO: implement search for isolated shells
        face,edge = -1,-1
        return face,edge
    ◇
```

Macro referenced in [23](#).

Face orientations storage In order to correctly accomplish the extraction of 3-cells from the 2-complex partition of the arguments’ space, it is necessary to use twice every 2-face, belonging with opposite orientations to the boundaries of two adjacent 3-cells. The array `faceOrientations`, initialized to $n \times 2$ zeros, with n equal to the number of 2-cells, is so used to store the orientations of faces considered as 2-cycles of edges.

In particular, the orientation of the 2-face is equivalent to the embedded orientation of one of its edges, corresponding either to the intrinsic orientation of this one, or to its opposite orientation. Hence, every time a face is used during the extraction of a 3-cell, (the elementary 1-chain of) one of its oriented edges is stored in `faceOrientations`, to remember its orientation, and eventually reverse the orientation of the face the next time it is used again. At the very end of the extraction algorithm, all the faces must be used twice, with opposite orientations.

```
<Face orientations storage 17> ≡
    """ Face orientations storage """
    def reverseOrientation(chain):
        return REVERSE([-cell for cell in chain])

Double check the faces boundaries made of edges Let us notice that a systematic use of the `FE` relation to compute the edges on the boundary of a face is *not* reliable when the faces are non-convex (WHY ??). A better solution is to double-check the result `FE[f]` when `len(FE[f]) > len(FV[f])`, in order to filter out the spurious edges ... The function below works with the precondition that vertices in `FV[f]` are spatially ordered along the face boundary.

```

⟨ Double check the faces boundaries made of edges 18b ⟩ ≡

3.6 Signed (co)boundary operator with non-contractible 2-cells

In this section we construct the matrix of the *signed* (i.e. oriented) boundary operator—with elements in $\{-1, 0, 1\}$ —in order to traverse efficiently the partial boundary of the

(coherently oriented) 3-cells to be reconstructed from a 2-skeleton embedded in 3D.

We start computing the 2-boundary / 2-coboundary using a triangulation of general LAR faces. The original LAR edges are uncoupled from those added by the triangulation algorithm. For the generation of the boundary triangulation matrix we do not use any geometric embedding (i.e. sign of determinants induced by vertex positions) but the standard sign rules of abstract simplicial complexes.

In particular, the 2-boundary matrix in the more general LAR cell setting is a contraction of a block-decomposition of the 2-boundary matrix built for the triangulated space. We cannot test for the 3-case because I do not have (for now :-) a tetrahedral CDT to apply to LAR 3-cells, but the method should extend naturally to higher dimensions.

Extend LAR edges with a given (2D) triangulation The function `extendEV` below extends the LAR edges, contained within the `EV` array, with the new arcs introduced by a given (2D) triangulation. The `TV` array contains, for each triangle, the list of its three vertex indices. The `ET` array, gives, for each triangle in the original edge array, the indices of incident triangles, already computed by the triangulation algorithm, invoked (please see the `test/py/bool/test16.py` example) by the `faceSlopeOrdering` function. The function return the new array of edges, as lists of vertex indices. The first n pairs are the original edges; the following ones are those added bu the triangulation. The dictionary `EVdict` is used to construct the returned output.

```
<Extend LAR edges with a given (2D) triangulation 20>≡
    """ Extend LAR edges with a given (2D) triangulation """
    from collections import OrderedDict

    def extendEV(EV,ET,TV):
        EVdict = OrderedDict([(edge,k) for k,edge in enumerate(EV)])
        n = len(EV)-1
        for e,(u,w) in enumerate(EV):
            for t in ET[e]:
                v1,v2,v3 = TV[t]
                v = list({v1,v2,v3}.difference([u,w]))[0]
                if u<v: newEdge = (u,v)
                else: newEdge = (v,u)
                if not newEdge in EVdict:
                    n += 1
                    EVdict[newEdge]=n

                if w<v: newEdge = (w,v)
                else: newEdge = (v,w)
                if not newEdge in EVdict:
                    n += 1
```

```

    EVdict[newEdge]=n
    return EVdict.keys()

```

Signed boundary operator for a general LAR 2-complex The function `larSignedBoundary` is our current implementation for the construction of the $p \times q$ matrix of the signed (i.e. oriented) boundary operator of the general LAR 2-complex in `larModel1`, starting from the $n \times m$ signed matrix of the LAR triangulation in `triaModel1`. The `FT` array provides, for each original LAR face, the list of triangle indices (to be used, for example, in `TV`) of its triangulation.

The `output` matrix is actually computed by first constructing the *unsigned boundary* operator, and then by updating its values by those provided by the contraction of the `input` columns corresponding to the subset of triangles associated to each original face.

No actual sum is necessary for the contraction of a set of `input` column to a single `output` column, because the nonzero elements corresponding to original edges are always located on different `input` rows. Conversely, the `input` rows corresponding to the edges added by the triangulation, located in the lower block of the `input` matrix, contain both one -1 term and one +1 term, that mutually cancel, so that their whole block can be implicitly removed from the `output` matrix.

```

⟨ Signed boundary operator for a general LAR 2-complex 21a ⟩ ≡
"""
Signed boundary operator for a general LAR 2-complex """
def larSignedBoundary(larModel, triaModel, FT):
    inputOp = signedSimplicialBoundary(*triaModel)
    outputOp = boundary(*larModel)
    (n,m),(p,q) = inputOp.shape, outputOp.shape

    for h in range(p): # for each LAR face
        for k,triangles in enumerate(FT):
            val = [inputOp[h,t] for t in triangles if inputOp[h,t]!=0.0]
            if val!=[]: outputOp[h,k] = val[0]
    return outputOp

```

Generation of random triangles The function `randomTriangles` returns the array `randomTriaArray` with a given number of triangles generated within the unit 3D interval. The `scaling` parameter is used to scale every such triangle, generated by three random points, that could be possibly located to far from each other, even at the distance of the diagonal of the unit cube.

The arrays `xs`, `ys` and `zs`, that contain the x, y, z coordinates of triangle points, are used to compute the minimal translation `v` needed to transport the entire set of data within the positive octant of the 3D space.

```
(Generation of random 3D triangles 37a) ≡
    """ Generation of random triangles """
    def randomTriangles(numberOfTriangles=400,scaling=0.3):
        randomTriaArray = [rtriangle(scaling) for k in range(numberOfTriangles)]
        [xs,ys,zs] = TRANS(CAT(randomTriaArray))
        xmin, ymin, zmin = min(xs), min(ys), min(zs)
        v = array([-xmin,-ymin, -zmin])
        randomTriaArray = [[list(v1+v), list(v2+v), list(v3+v)] for v1,v2,v3 in randomTriaArray]
        return randomTriaArray
    ◇
```

Generation of a random 3D point A single random point, codified in floating point format, and with a fixed (quite small) number of digits, is returned by the `rpoint3d()` function, with no input parameters.

```
(Generation of a random 3D point 37c) ≡
    """ Generation of a random 3D point """
    def rpoint3d():
        return eval( vcode([ random.random(), random.random(), random.random() ] ) )
    ◇
```

Macro referenced in [36a](#).

Generation of a single random triangle A single random triangle, scaled about its centroid by the scaling parameter, is returned by the `rtriangle()` function, as a tuple of two random points in the unit square.

```
( Generation of a single random triangle 38a ) ≡
    """ Generation of a single random triangle """
    def rtriangle(scaling):
        v1,v2,v3 = array(rpoint3d()), array(rpoint3d()), array(rpoint3d())
        c = (v1+v2+v3)/3
        pos = rpoint3d()
        v1 = (v1-c)*scaling + pos
        v2 = (v2-c)*scaling + pos
        v3 = (v3-c)*scaling + pos
        return tuple(eval(vcode(v1))), tuple(eval(vcode(v2))), tuple(eval(vcode(v3)))
    ◇
```

Containment boxes Given as input a list `randomTriaArray` of pairs of 2D points, the function `containmentBoxes` returns, in the same order, the list of *containment boxes* of the input lines. A *containment box* of a geometric object of dimension d is defined as the minimal d -cuboid, equioriented with the reference frame, that contains the object. For a 2D line it is given by the tuple (x_1, y_1, x_2, y_2) , where (x_1, y_1) is the point of minimal coordinates, and (x_2, y_2) is the point of maximal coordinates.

```
( Containment boxes 38b ) ≡
    """ Containment boxes """
    def containmentBoxes(randomPointArray,qualifier=0):
        if len(randomPointArray[0])==2:
            boxes = [eval(vcode([min(x1,x2), min(y1,y2), min(z1,z2),
                                max(x1,x2), max(y1,y2), max(z1,z2)])) + [qualifier]
                     for ((x1,y1,z1),(x2,y2,z2)) in randomPointArray]
        elif len(randomPointArray[0])==3:
            boxes = [eval(vcode([min(x1,x2,x3), min(y1,y2,y3), min(z1,z2,z3),
                                max(x1,x2,x3), max(y1,y2,y3), max(z1,z2,z3)])) + [qualifier]
                     for ((x1,y1,z1),(x2,y2,z2),(x3,y3,z3)) in randomPointArray]
        elif len(randomPointArray[0])==4:
            boxes = [eval(vcode([min(x1,x2,x3,x4), min(y1,y2,y3,y4), min(z1,z2,z3,z4),
                                max(x1,x2,x3,x4), max(y1,y2,y3,y4), max(z1,z2,z3,z4)])) + [qualifier]
                     for ((x1,y1,z1),(x2,y2,z2),(x3,y3,z3),(x4,y4,z4)) in randomPointArray]
        return boxes
    ◇
```
